Abstract. We review the observational evidences and the possible theoretical explanations for the abundance gradients in the Galactic disk. In particular, we discuss the implications of abundance gradients and gradients of abundance ratios on the mechanism for the formation of the Galaxy. We conclude that an **inside-out** formation of the Galaxy, and in particular of the Galactic disk, where the innermost regions are assumed to have formed much faster than the outermost ones, represents the most likely explanation for abundance gradients and we predict that the abundance gradients along the Galactic disk have increased with time.

1 Introduction

The existence of abundance gradients along the Galactic disk seems now to be well established with agreement between different data sources.

- **HII regions:** Shaver et al. (1983) first measured abundance gradients from Galactic HII regions indicating that O/H, N/H, Ar/H show gradients of the order of $-0.07 \text{ dex Kpc}^{-1}$ between 4 and 14 Kpc along the Galactic disk. More recently, Vilchez and Esteban (1996) found a flattening of O/H, N/H and S/H gradients for $R_{GC} > 12 \text{ Kpc}$ suggesting that these gradients present a bimodal behaviour.
- **Planetary Nebulae:** Maciel and Chiappini (1994) and Maciel and Quireza (1998) found O/H, Si/H, Ne/H, Ar/H gradients from planetary nebulae very similar to those found from HII regions, namely between $-0.04 - -0.07 \text{ dex Kpc}^{-1}$ in the galactocentric distance range 4 - 14 Kpc.
- **B type stars:** Kaufer et al. (1994) found that B type stars did not exhibit any appreciable gradient but more recent studies (Smartt and Rolleston, 1997 and Gummersbach et al. 1998) found a gradient of oxygen of $-0.07 \pm 0.01 \text{ dex Kpc}^{-1}$ between 6 and 18 Kpc and $-0.07 \pm 0.02 \text{ dex Kpc}^{-1}$ between 5 and 14 Kpc, respectively. These results agree with the gradient estimated by Shaver et al. (1983) from HII regions and with the planetary nebula data.
- **Open clusters:** as indicated in the review by Friel (1995) the iron abundance in open clusters shows a gradient of [Fe/H] of $-0.095 \pm 0.017 \text{ dex Kpc}^{-1}$ between 7 and 16 Kpc but Friel (1998) showed a more recent determination

of the $[\text{Fe}/\text{H}]$ gradient shallower than the previous one and closer to the O gradients as estimated recently from B type stars .

It is therefore encouraging that different data sources seem to agree at least on the value of the oxygen gradient. However, we would be careful in concluding that the gradients of all the other heavy elements (C, N, Fe, Ar. etc..) should be the same as oxygen since from a theoretical point of view we would expect small differences due to the different nucleosynthetic production mechanisms and different progenitors of the elements, as we will see in the next paragraphs.

The question we should ask now is : *how can we obtain abundance gradients along the Galactic disk?*

Several mechanisms have been proposed in the last years:

- i) Variations in the gas fraction as a function of the galactocentric distance R_{GC} (original idea of the “simple model”) but the predicted gradients are too flat compared to observations (Pagel 1989).
- ii) Variations in the initial mass function (IMF) but most of the suggested variations (massive stars increase with decreasing metallicity Z) tend to destroy the gradient! Carigi (1996) tried the opposite case, where low mass stars increase with decreasing metallicity, and showed that steep abundance gradients can be obtained but that the same model does not fit the chemical evolution of the solar neighbourhood. However, before concluding that there is no viable solution with a variable IMF we should try to test the variation of the IMF recently proposed by Larson (1998) who suggested a variation in the lower mass cut-off with galactocentric distance rather than a variable slope.
- iii) Metal dependent stellar yields a la Maeder (1992) (less metals are produced at higher Z) produce shallow gradients along the Galactic disk, as it has been shown by several papers (Giovagnoli and Tosi, 1995; Carigi 1996), which do not agree with the most recent observational estimates.
- iv) Variations in the efficiency of star formation ($SFR = \nu(R_{GC})\sigma_{gas}^k$). Prantzos and Aubert (1995) explored this possibility by assuming $\nu \propto R_{GC}^{-1}$ and found shallow gradients, again too shallow if compared with the most recent data.
- v) Variations of the star formation rate (SFR) relative to the infall rate (IR), namely SFR/IR , with R_{GC} . This hypothesis is also known as **biased infall** since one can obtain such a situation by assuming that the Galactic disk formed by infall of gas occurring at a faster rate in the innermost regions than in the outermost ones. The physical reason for a biased infall can be found in the fact that the gas tends to collapse more quickly in the center of the spheroid so that a gradient in the gas density, being lower in the more external parts, is established. In this situation the gas which continues to infall towards the disk falls more efficiently towards the center than towards the external regions, due to the stronger tidal force acting at the center (see also Larson 1976). Several authors showed that the biased infall can well

reproduce steep abundance gradients along the disk, especially if coupled with a star formation rate proportional to some power k of the gas density $SFR \propto \sigma_{gas}^k$ with $k > 1$ (Tosi 1988; Matteucci and François 1989; Matteucci et al. 1989; Chiappini et al. 1997). Therefore, we consider this as a viable solution to explain the existence of abundance gradients.

- vi) Radial flows along the Galactic disk are not enough by themselves to produce steep gradients but they work well if coupled with biased infall or a threshold in the SFR under specific conditions (Clarke 1989; Sommer-Larsen and Yoshii 1989; Goetz and Koeppen 1992; Chamcham and Tayler 1994, Edmunds and Greenhow 1995).
- vii) A biased outflow assuming a stronger and earlier wind in the external regions than in the internal ones can also produce steep abundance gradients, as shown for elliptical galaxies by Martinelli et al. (1998). At this point one could ask : *how can we distinguish between biased infall and biased outflow?*. There is a clear way to do it: thru the abundance ratios. In fact, under the biased infall hypothesis the predicted present time $[\alpha/Fe]$ ratios tend to decrease with galactocentric distance. This is due to the fact, as shown by Matteucci (1992), that if a region of the Galaxy evolves slower than another one then, at the same $[Fe/H]$, the slow region will show a lower $[\alpha/Fe]$ ratio, due to the longer timescale required to achieve the same $[Fe/H]$ relative to the fast region and therefore to the larger contribution from type Ia supernovae which are responsible for the bulk of iron production (Greggio and Renzini, 1983; Matteucci and Greggio 1986), at that given $[Fe/H]$. On the other hand, under the biased outflow hypothesis Martinelli et al. (1998) predicted that the $[\alpha/Fe]$ ratio increases with the galactocentric distance, due to the fact that the galactic wind occurs before in the external regions than the internal ones, and that it is likely that no more or negligible star formation has taken place after the wind event. As a consequence of this, the stars in the external regions will not show the iron contributed by supernovae of type Ia but rather that produced by massive stars. In order to decide which one is the mechanism responsible for the abundance gradients in the Galactic disk one should check the gradient of the $[\alpha/Fe]$ ratio.

In the following sections we will describe examples of biased infall models for the chemical evolution of the Galactic disk and compare their predictions with the available data. In particular, we will discuss abundance gradients of several chemical elements and of their ratios and by comparing these results with observations we will try to infer some conclusions on the mechanism of formation of the Galaxy.

2 Chemical Evolution Models

The Matteucci and François (1989)(hereafter MF) model assumes that the Galactic disk is divided in several independent rings 2 Kpc wide with no exchange of

matter between them. It assumes also that the disk forms out of infall of primordial gas which has accumulated with different timescales at different galactocentric distances. The galactic halo represents the earliest phase of this infall process and no clear distinction between halo and disk is present. In particular, the assumed law for the disk formation is a linear relation between τ and R_{GC} :

$$\tau(R_{GC}) = 0.464R_{GC} - 1.59 \quad (1)$$

It is worth mentioning that a quadratic or exponential law for τ does not produce relevant differences, as shown by Carigi (1996), in the predicted abundance gradients. The adopted stellar yields are independent of metallicity and the star formation rate is proportional to both the surface gas density and the total surface mass density, $\text{SFR} \propto \sigma_{gas}^k \sigma_{tot}^h$. Matteucci and François concluded that a good fit to the observed abundance gradients (Shaver et al. 1983) and gas distribution in the disk requires $k=1.1$ and $h=0.1$.

Chiappini's et al. (1997) (hereafter CMG) model is a two-infall model, in the sense that assumes that the halo and the thick disk formed much more quickly than the thin disk during a first infall episode, whereas the thin disk formed by means of a second completely independent episode of primordial infalling gas. In particular, the timescale for the formation of the halo-thick disk is $\tau_H \sim 1$ Gyr and does not vary significantly with the galactocentric distance whereas the timescale for the thin disk (τ_D) varies as:

$$\tau_D(R_{GC}) = 0.875R_{GC} - 0.75 \quad (2)$$

In this approach the evolution of the halo-thick disk is completely disentangled from that of the thin disk. The star formation rate is the same as in MF except that $k = 1.5$ and $h = 0.5$. It is worth noting that the higher k value adopted by CMG together with the longer timescale for the thin disk formation (8 Gyrs for the solar vicinity) ensures a good fit of the reviewed G-dwarf metallicity distribution by Rocha-Pinto and Maciel (1996). Moreover, this choice for the star formation exponent is in agreement with recent estimates of the star formation rate in spirals by Kennicutt (1998). This model also adopts a threshold surface gas density ($\sigma_{gas} = 7M_{\odot}pc^{-2}$) for the star formation rate (Kennicutt, 1989) which naturally produces a hiatus in the star formation rate between the end of the thick disk phase and the beginning of the thin disk phase. Such a hiatus seems to be real since it is observed either in the plot of $[\text{Fe}/\text{O}]$ versus $[\text{O}/\text{H}]$ (CMG) or in the plot of $[\text{Fe}/\text{Mg}]$ versus $[\text{Mg}/\text{H}]$ (Bernkopf and Fuhrmann, 1998). As we will see, the assumed threshold is also responsible for the flatter than MF's gradients in the inner thin-disk regions and the very flat gradients in the outermost thin-disk regions. Chamcham and Tayler (1994) also found a bimodal gradient due to the adoption of a threshold in the star formation rate.

2.1 Basic Equations

The basic equation in both models (MF and CMG) are:

$$\begin{aligned}
 \frac{d G_i(r, t)}{dt} = & -X_i(r, t) \Psi(r, t) + \int_{M_L}^{M_{Bm}} \Psi(r, t - \tau_M) (Q_M)_i \Phi(M) dM + \\
 & A \int_{M_{Bm}}^{M_{BM}} \Phi(M_B) \left[\int_{\mu_m}^{0.5} f(\mu) \Psi(r, t - \tau_{M2}) (Q_{M1})_i (t - \tau_{M2}) d\mu \right] dM_B \\
 & + (1 - A) \int_{M_{Bm}}^{M_{BM}} \Psi(r, t - \tau_{MB}) (Q_{MB})_i (t - \tau_{MB}) \Phi(M_B) dM_B \\
 & + \int_{M_{BM}}^{M_U} \Psi(r, t - \tau_M) (Q_M)_i (t - \tau_M) \Phi(M) dM + (X_i)_{inf} \frac{d G(r, t)_{inf}}{dt} \quad (3)
 \end{aligned}$$

In CMG the infall term is defined as:

$$\frac{d G_i(r, t)_{inf}}{dt} = \frac{A(r)}{\sigma(r, t_G)} (X_i)_{inf} e^{-t/\tau_H} + \frac{B(r)}{\sigma(r, t_G)} (X_i)_{inf} e^{-(t-t_{max})/\tau_D} \quad (4)$$

where $G_i(r, t)_{inf}$ is the normalized surface gas density of the infalling material in the form of the element i , $(X_i)_{inf}$ gives the composition of the infalling gas which is assumed to be primordial. t_{max} is the time of maximum gas accretion onto the disk, and τ_H and τ_D are the timescales for the mass accretion in the halo and disk components, respectively. These are the two really free parameters of the model and are constrained mainly by comparison with the observed metallicity distributions for halo and disk stars. The t_{max} value is chosen to be 2 Gyrs and roughly corresponds to the end of the halo-thick disk phase. The quantities $A(r)$ and $B(r)$ are derived by the condition of reproducing the current total surface mass density distribution in the halo and the disk, respectively. The current total mass distribution is taken from Rana (1991).

In the previous model of MF the infall term was simply:

$$\frac{d G_i(r, t)_{inf}}{dt} = \frac{A(r)}{\sigma(r, t_G)} (X_i)_{inf} e^{-t/\tau} \quad (5)$$

with a unique τ for the halo and the disk and where $A(r)$ was chosen under the condition of reproducing the present time total surface mass density in the disk. In both the models the adopted IMF is taken from Scalo (1986).

3 Model Predictions

A good model for the chemical evolution for our Galaxy should honour a minimal number of observational constraints both in the solar neighbourhood and in the whole disk. Both the models described above were tested to reproduce the following constraints in the solar vicinity: i) the relative number of disk and halo stars in the solar cylinder, ii) the present day gas fraction, iii) the type Ia and II supernova rates and their ratio, iv) the solar abundances, v) the age-metallicity relation, vi) the present day infall rate, vi) the G-dwarf metallicity distribution,

vii) the [el/Fe] versus [Fe/H] relations. Under these conditions MF concluded that good abundance gradients in agreement with the Shaver et al. (1983) data, which agree with the most recent estimates, are reproduced by assuming an **inside out** formation of the disk, as described by equation (1). In addition, they showed that the star formation law should have $0 < k \leq 1.5$ with a best value of $k = 1.1$ in order to reproduce, at the same time, abundance gradients and an acceptable distribution of the surface gas density along the disk. In fact, the gas distribution along the disk strongly depends on the assumed power of the surface gas density in the star formation law. The predicted gradients, in the galactocentric distance range 4-14 Kpc, are: $\frac{\Delta \log(O/H)}{\Delta R_{GC}} = -0.065$ dex Kpc⁻¹; $\frac{\Delta \log(^{12}C/H)}{\Delta R_{GC}} = -0.066$ dex Kpc⁻¹; $\frac{\Delta \log(^{14}N/H)}{\Delta R_{GC}} = -0.085$ dex Kpc⁻¹; $\frac{\Delta \log(Fe/H)}{\Delta R_{GC}} = -0.07$ dex Kpc⁻¹; $\frac{\Delta \log(^4He/H)}{\Delta R_{GC}} = -0.0085$ dex Kpc⁻¹. As we can see, most of these gradients are in agreement with the most recent estimates. An interesting fact is that gradients of different elements are slightly different and this is due to the different nucleosynthesis history of each element. For example ¹⁴N, which is mostly produced in low and intermediate mass stars as a partly primary and partly secondary (proportional to the original abundances of O and C) element, shows a steeper gradient than oxygen which is mostly produced in massive short lived stars. In addition, the fact of having a secondary nature plays a role in defining the absolute value of the abundance gradient. The gradient of Fe is also slightly steeper than that of oxygen since iron is mostly produced on long timescales by type Ia SNe (white dwarfs in binary systems). Therefore, both the timescales and the primary/secondary nature of a chemical element play a role in defining its gradient along the Galactic disk.

CMG predicted the existence of bimodal gradients along the Galactic disk, in the sense that their gradients are flatter in the outermost regions and steeper in the internal ones ($R < 10$ Kpc), in agreement with Vilchez and Esteban (1996). In particular, their gradients, in the range 4-14 Kpc, are:

$\frac{\Delta \log(O/H)}{\Delta R_{GC}} = -0.032$ dex Kpc⁻¹ in the inner region and $\frac{\Delta \log(O/H)}{\Delta R_{GC}} = -0.018$ dex Kpc⁻¹ in the outer region, $\frac{\Delta \log(^{14}N/H)}{\Delta R_{GC}} = -0.037$ dex Kpc⁻¹ in the inner region and $\frac{\Delta \log(^{14}N/H)}{\Delta R_{GC}} = -0.028$ dex Kpc⁻¹ in the outer region, $\frac{\Delta \log(Fe/H)}{\Delta R_{GC}} = -0.04$ dex Kpc⁻¹ in the inner region and $\frac{\Delta \log(Fe/H)}{\Delta R_{GC}} = -0.017$ dex Kpc⁻¹ in the outer region.

The gradients are all flatter than those predicted by MF and the main reason resides in the fact that CMG adopted a threshold surface gas density below which the star formation is assumed to stop. This mechanism acts mostly in the external regions where the amount of gas is almost always close to the threshold. However, the best model of CMG predicts a gas distribution along the disk (see figure 2) in better agreement than that predicted by MF and this is also due to the assumed threshold in the star formation rate.

3.1 Abundance gradients and variable IMF

An alternative explanation for the formation of abundance gradients is a variable IMF, as discussed in the introduction. In figure 1 we show the predicted gradient of oxygen by the best model of CMG (Model A), by a model considering an IMF which predicts more massive stars in lower density regions (Padoan et al. 1997) (Model B) and the predictions of Model C where both the variable IMF and the variable star formation efficiency are considered. The star formation efficiency is assumed to increase with decreasing R_{GC} as in Prantzos and Aubert (1995). It is clear that a variable IMF of this kind tends to destroy the gradient unless the additional hypothesis of the variable star formation efficiency is considered. However, as shown in figure 2, this last model (Model C) does not fit at all the observed gas distribution along the disk and therefore it should be rejected.

Fig. 1. The predicted oxygen abundance along the Galactic disk by three different models

Fig. 2. Observed and predicted gas distribution along the Galactic disk. The data and the models are indicated in the figure.

4 Discussion and conclusions

In this paper we have shown that the most realistic scenario to explain abundance gradients along the Galactic disk is the **inside-out** formation of the disk, in the sense that the internal parts of the disk are assumed to have formed on shorter timescales than the external parts. This allows us to reproduce gradients in agreement with the observations as long as the exponent of the star formation law, k , is larger than unity. At the same time we can reproduce the observed gas distribution along the disk as long as $k \leq 1.5$. Therefore, we can envisage a range of possible values for k , namely $1.1 \leq k \leq 1.5$. Better agreement is obtained if also a dependence on the total surface mass density is considered in the star formation law (see also Tosi 1988).

Concerning the gas distribution along the Galactic disk, we showed that the assumption of a threshold in the star formation rate improves the agreement with observations although it predicts slightly too shallow gradients, at least in the light of the more recent data.

The assumption of a variable IMF where massive stars are more abundant in

low metallicity, low density regions tend to destroy the gradient along the disk, at variance with observations, although we can not exclude the existence of a particular variation of the IMF which can reproduce all the main observational constraints.

Therefore, our main conclusion is that an inside-out scenario with constant IMF is the most favoured for the formation of abundance gradients.

In order to check this point we should try to observe $[\alpha/\text{Fe}]$ ratios in stars in the outermost disk regions. In fact, we have also shown that one should expect differences (although small) between the gradients of elements produced on different timescales. For this reason we expect that the $[\alpha/\text{Fe}]$ ratio has a **negative** gradient with increasing R_{GC} , and future measurements of such a ratio at large galactocentric distances can assess this point. Recently, Nissen and Schuster (1997) identified metal rich halo stars ($[\text{Fe}/\text{H}] \sim -1$ dex) with both high and low $[\alpha/\text{Fe}]$ ratios. The halo stars with low $[\alpha/\text{Fe}]$ ratios tend to be on orbits biased to the outer halo. This could be the consequence of the inside-out Galaxy formation, in the sense that the outer halo formed more slowly than the inner one in analogy with what happens in the disk. In particular, we predict that the stars in the outer disk should show this effect even more than the outer halo stars.

Another important fact, strictly related to the mechanism of Galaxy formation, is the evolution of gradients with time. On this point there is no general agreement between different data sources and different authors!

From the observational point of view the situation can be summarized as follows:

- **Planetary nebulae** seem to suggest that gradients steepen with time (Maciel and Koeppen 1994); in fact, type III PNe (the oldest) have a flatter gradient than type II and I PNe, but dynamical effects could perhaps be responsible for this behaviour.
- **Open Clusters** suggest no clear variation of gradients with time, and may be a flattening (Carraro et al. 1998), but again dynamical effects could have played a role.

From the theoretical point of view some models predict a steepening of the gradients with time (Tosi 1988; MF; Goetz and Koeppen 1992; CMG) whereas others predict the opposite trend (Ferrini et al. 1994; Allen et al. 1998). Generally, models with biased infall (inside-out formation of the disk), such as those discussed here, predict a steepening of gradients in time due mainly to the assumed long infall timescales at large galactocentric distances (see also the review of Tosi 1996). Clearly the evolution of gradients with time is strictly related to the mechanism of Galaxy formation and is an important point to assess. However, given the situation, it is still premature to draw firm conclusions and more precise observational data are necessary.
